COMPLETE SPECIFICATION.

Improvements in or relating to Object Detection Systems.

We, WILMOT-BREEDEN LIMITED, a British Company, of Amington Road, Birmingham, 25, do hereby declare the invention, for which we pray that a patent may be granted 5 to us, and the method by which it is to be performed, to be particularly described in and by the following statement:—

This invention relates to object detection devices for detecting an earthed object by 10 the change in capacitance to earth of a capacitive electrode when the body is in the neighbourhood of the electrode. As will be apparent from the following description, the invention finds particular application in 15 the guarding of machine tools and the like to ensure the safety of the operator.

In general with capacitance type object detection systems heretofore, a problem arises that the capacitance between the hand 20 or arm or any other earthed object and the electrode is in shunt with the leakage capacitance between the electrode and earthed bodies. This is a particularly serious problem in a machine tool which is normally 25 made of metal and in which the capacitance electrode loop should extend around the whole opening through which access can be obtained to the moving parts. In such circumstances, there would normally be a 30 very substantial capacitance between the electrode and the earthed metal structure of the machine. If the aperture is large, the presence of a hand within the aperture may give only a very small change in the 35 capacitance between the electrode and earth. Such small changes in capacity can be detected and measured by means of capacitance measuring bridges but this requires a bridge of long term stability if frequent 40 re-adjustment is to be avoided. Problems

also arise due to the temperature coefficient of capacitance to earth of the lead connecting the electrode to the measuring equipment. If a screened cable is used to minimise variations of capacitance between the connecting lead and earth, then this screening in the cable introduces a very large capacitance between the connecting lead and earth. In a typical capacitance detection system for controlling a guard for a machine tool, it has been found that the electrode had a capacitance to earth of 20 picofarads whilst the connecting screened cable had a capacitance of 200 picofarads. The change in capacitance introducing a hand into the 45 centre of a rectangular loop of 20" x 10" was only 1 picofarad. It will be seen therefore, with such systems, it has been necessary heretofore to have electrical equipment 50 which is accurately responsive to very small changes in a large capacitance and it is necessary also to ensure the stability of this large capacitance and of the equipment detecting the change in capacitance.

According to the present invention, a 55 capacitance type object detection system for detecting the presence of an earthed object within an opening forming an entry to a region to be guarded comprises an elongated electrode extending around at least part of the periphery of said opening, the electrode being in the form of a strip with one of its faces facing across said opening, a conductive screen for said electrode extending around the other face of the electrode to surround the whole electrode behind the plane of said one face, and a three-terminal 60 impedance measuring circuit arranged to give an output signal responsive to changes 65 in the capacity between said electrode and 70

75 80

[Price 4s. 6d.]

earth whilst "seeing off" any capacitance between the electrode and the screen. Three terminal measuring circuits, particularly transformer ratio-arm bridges are well known and have the property that an output signal can be obtained dependent on the impedance between two terminals whilst being unaffected by any impedance between either of these two terminals and the third terminal. In the present case, the third terminal is connected to the screen and, of the other two terminals, one is earthed and the other connected to said electrode.

The aforementioned electrode may be in the form of a metal strip forming a closed loop extending around the region in which the presence of an earthed body is to be detected and with the plane of the strip parallel to the axis of the aperture defined by the loop. The screen is preferably then also a strip of slightly greater width than the electrode and extending around the electrode on the outer side thereof and preferably also having flanges extending inwardly of the aperture to shield the edges of the electrode strip.

More generally, if a single closed loop electrode is used to guard a region, the loop need not be in a flat plane; its plane may be shaped to conform to the shape of the region to be guarded.

It is not essential however for the electrode completely to surround the opening. It is possible for example to have two electrodes facing one another or to have an electrode curved in the form of an arc, e.g. a semi-circle so as partially to surround a region to be guarded.

Preferably the or each electrode is covered with insulating material. In a machine tool, the or each electrode may be so positioned or arranged that it cannot be touched by an operator's hand or other earthed body.

The three-terminal impedance measuring circuit may conveniently be a capacitance detection device comprising a source of alternating voltage, one terminal of which is earthed and the other terminal of which is connected by a lead, referred to herein-after as the neutral line, to one input of an alternating current detector the other input terminal of which is connected by the inner conductor of a co-axial cable to said electrode, the outer conductor of the co-axial cable being connected to said screen and to said neutral line and a balancing circuit for feeding alternating current into said detector to balance the alternating current due to the presence of an earthed body having capacitance between the body and said electrode or electrodes. The capacitance detection device forms a three-terminal capacitance bridge in which any capacitance between the screen and earth is charged from said voltage source and does

not affect the detector. The capacitance of the co-axial line is in shunt across the input to the detector and since, when the system is balanced, there is no voltage across this input, the capacitance of the cable is immaterial. The bridge can be balanced when there is no earthed body adjacent the electrode or electrodes and it will then give no output until an earthed body near the electrode or one of the electrodes gives a capacitance between that electrode and earth.

The screen around the or each electrode can readily be arranged to eliminate most of the capacitance between the electrode and earth. The use of the three-terminal measuring circuit eliminates the effect of the capacitance of the cable and, since the balancing circuit may very simply be readjusted if necessary, the long term stability problems are eliminated.

The invention thus includes within its scope a capacitance type object detection system for detecting the presence of an earthed object comprises a closed loop electrode extending around the region within which the presence of an earthed object is to be detected, and a conductive screen extending around the outer side of said closed loop electrode and closely adjacent thereto so as to lie between the electrode and any surrounding body in combination with a capacitance detection device comprising a source of alternating voltage, one terminal of which is earthed and the other terminal of which

is connected by a lead, referred to herein-after as the neutral line, to one input terminal of an alternating current detector the other input terminal of which is connected by the inner conductor of a co-axial cable to said electrode, the outer conductor of the co-axial cable being connected to said screen and to said neutral line and a balancing circuit for feeding alternating current into said detector to balance the alternating current due to the presence of an earthed body having capacitance between the body and said electrode.

Most conveniently the detector comprises a high gain amplifier with a feedback circuit for providing a feedback current to the input of the amplifier; this feedback provides gain stability for the amplifier and increases the input impedance, thus giving an amplifier of the required characteristics.

The output voltage from the amplifier or the feedback current may be used as a measure of the capacitance. Conveniently the output voltage is applied to a phase sensitive detector having a reference signal derived from the alternating current source. This phase sensitive detector gives a direct current output which may be used for example to operate a relay.

Although the screen around the electrode cannot eliminate all the capacitance between

70

120

125

130

the electrode and the earth, it can readily be arranged to eliminate most of this capacitance and, in the example quoted above, the introduction of such a screen can reduce 5 the capacitance between a rectangular electrode of 20" x 10" from 20 picofarads to 4 picofarads. More important however, the use of the three terminal measuring equipment eliminates the effect of the capacitance 10 of the cable and thus a change of 1 picofarad in capacitance due to the presence of a hand in the aperture is a change of 25% in the original capacity, the effect of which has to be balanced out by the balancing 15 circuit. With such a large change, the long term stability problems encountered in capacitance type detection equipment heretofore are eliminated.

Balancing may be achieved by a balancing 20 circuit fed from the aforesaid alternating voltage source by means of a ratio transformer, the ratio transformer providing an alternating voltage in opposite phase but in known ratio to the voltage between the 25 neutral line and earth. This voltage is applied between the neutral line and one terminal of an adjustable balancing capacitor the other terminal of which is connected to the input terminal of the aforementioned 30 amplifier.

The invention is particularly applicable 35 to the control of a safety guard for a power operated tool. For such a tool, there has to be a relatively large aperture providing access to the moving parts. With the arrangement of the present invention, the presence of an operator's hand anywhere within the aperture can readily be detected and the device can be used, in the manner 40 described in the Application No. 36071/64 (Serial No. 1,106,456) to provide a signal whenever the operator's hand is in this aperture. Furthermore as is described in the aforementioned application, the change 45 in this signal when the hand is withdrawn can be used automatically to effect the closing of a mechanical guard and thereby operation of the tool or other machinery so that an operator merely has to put the 50 work piece in position and withdraw his hands thereby initiating the operation of the machine whilst providing a full safeguard against any operation of the machine whilst the operator's hand or arm is within 55 the aperture.

In one arrangement for use on a machine 60 tool, a mechanical guard is provided comprising two gates movable towards one another to close an opening and two electrodes are arranged on the gates facing across the opening when the gates are apart, the electrodes being connected in parallel to the three-terminal impedance measuring circuit. The gates may be arranged to 65 overlap when closed and, in this case, the electrodes are preferably arranged to face one another when the gates are open so as to define a plane in which any earthed body is detected. The electrodes, with their screens, may be mounted in or embedded in insulating material. This material may be for example, rubber or a resilient plastic. In this construction, as in the other machine tool guards to be described, the electrode system and measuring circuit may be used to give a guard signal to prevent operation of the machine if any earthed body is in the opening. The arrangement of the present invention is particularly applicable to systems in which the withdrawal of an earthed body, usually the operator's hand, automatically initiates operation of the machine. The signal may be used for example to initiate closing of a mechanical guard which has to be closed before a tool or the like can be actuated within the enclosed region. If desired, separate electrode systems may be provided for performing both guarding and triggering functions.

As another example of the application of the invention, in a moulding machine or the like in which two die plates are brought together, to guard against the presence of an earthed body between the die plates, electrodes may be arranged around or partly around each of the die plates, the electrode or electrodes around one die plate facing the electrode or electrodes around the other. Each of the two electrode systems employed might be a closed loop, typically of square 100 or rectangular form mounted on the die plate or the platen carrying the die plate. It is not necessary however to have a closed loop and each electrode system might comprise two or more straight or curved electrodes arranged around the periphery of the die plate or platen.

The following is a description of a number of embodiments of the invention, reference being made to the accompanying drawings in which:—

Figure 1 is a front view of a press embodying guard means operated by an earthed body capacitance type detection system;

Figure 2 is a transverse section through the electrode system in Figure 1;

Figure 3 is a diagram illustrating the detection system used in the press of Figure 1;

Figure 4 is a perspective view of a riveting press;

Figure 5 is a diagram illustrating the detection system used in the arrangement of Figure 4;

Figure 6 is a diagrammatic perspective view illustrating guard electrodes on a 125 moulding machine;

Figure 7 is a diagram illustrating the use of a pair of electrodes for guarding a region;

Figure 8 is a section along the line 8—8 of Figure 7;

Figure 9 is a sectional view through a pair of guard gates for a machine tool; and

Figure 10 is a perspective view illustrating another electrode arrangement for guarding part of a machine.

Referring to Figure 1, there is shown a press having a ram 1 driven by eccentrics 2 on a crankshaft 3. Guarding of the press is effected by a glazed front guard 4 on vertical hinges, fixed wire mesh side guards 5 and a pair of vertically slideable gates 6 for closing an opening 7 in the front guard 4. Only one of the gates 6 is shown in Figure 1. Reference may be made to the specification of co-pending Application No. 36071/64 (Serial No. 1,106,456) for a fuller description of such a construction of guards for a press.

The main body structure of the press is of metal and is electrically earthed. This earthed structure is indicated diagrammatically at 10 in Figures 2 and 3. When the gates 6 are open, the operator can obtain access to the moving parts through the opening 7. This opening, at its outer end, is surrounded by a closed loop metal electrode 14 in the form of a strip extending completely around this opening. Closely adjacent this strip and surrounding it is a metallic screen 15 which is slightly wider than the strip and which has flanges extending around the edges of the strip. This screen 15 serves to reduce the capacitance between the electrode and the earthed body of the machine although introducing a substantial capacitance between the electrode 14 and the screen 15.

The present invention is concerned more particularly with the detection of an earthed object within the region surrounded by the electrode 14. The electrode 14 is connected by the inner conductor 16 of a co-axial cable 17 to a capacitance sensing device indicated generally at 18 in Figure 3. The screen 15 is connected to the outer conductor of this co-axial cable.

The device 18 includes an oscillator 20 providing an alternating current which is applied to a primary winding 21 of a transformer 22 having closely coupled secondary windings 23, 24. These windings provide two output voltages in known ratio; typically the winding 23 will have ten times as many turns as the winding 24. The two windings are connected in series and the junction of these two windings is connected to a lead 25 referred to hereinafter as a neutral line. The other end of the winding 23 is earthed. The screen of the co-axial cable 17 is connected to the neutral line 25. This neutral line is also connected to one input terminal of an amplifier 26. The other input terminal is connected to the inner conductor 16 of the co-axial cable 17.

The winding 24 applies a voltage to one

terminal of adjustable capacitor 27, the other terminal of which is connected to the input terminal of the amplifier. The amplifier has a feedback circuit which includes an impedance 28. The capacitor 27 is adjusted, when no earthed body is within or adjacent the loop electrode 14, so as to provide an input current substantially balancing any residual input from the electrode 14 due to stray capacitance between this electrode and earth. By making winding 23 with more turns than winding 24, the capacitor 27 has to have a larger capacitance than the capacitance being balanced out and it is thus readily possible to construct a suitable adjustable capacitor 27. This capacitor is adjusted so that, in the absence of any earth body adjacent the electrode 14 there is negligible output voltage from the amplifier 26. When a hand is put near the electrode 14 however, because the hand is earthed, there is an appreciable current introduced into the amplifier and this changes the output voltage. This output voltage is applied to a phase sensitive detector 30 which has a reference alternating current signal derived from a further winding 31 on the transformer 22. The phase sensitive detector gives a direct voltage output which is applied to a d.c. amplifier 32 and this may typically be used to operate a relay or an electronic trigger circuit in a control circuit 33. The control circuit is arranged so that, whenever an earthed body such as the operator's hand or arm is removed from the electrode aperture, when gates 11, 12 are open, closing of the gates is triggered and operation of the machine is initiated, as is described in the aforementioned Application No. 36071/64 (Serial No. 1,106,456). Reference may be made to that specification for a fuller description of a suitable control circuit which is responsive to a switch 34 on the crankshaft 3 for ensuring the gates can-

not be opened until the ram 1 is in its uppermost position, and a switch 35 on the gates 6 to ensure that the machine cannot be operated until the gates are fully closed. The operation of the gates 6 is effected by a pneumatic cylinder 36 to which air is admitted by a solenoid-operated valve 37 controlled by the control circuit 33.

Figure 4 illustrates a riveting press which cannot be completely enclosed with mechanical guards because open access is required during operation for a workpiece 40, which is to be riveted, to extend into the region under the riveting tool 41. In this embodiment of the invention, a semi-circular electrode system 42 is provided with a screen shaped to give a detection region lying within the arc of the electrode and of small dimension in the vertical plane so that it can detect earthed objects in the region im-

70

130

mediately above the workpiece 40. In this type of machine, no mechanical guard can be used and the earthed body detection system is used therefore directly to inhibit the 5 operation of the machine. Figure 5 is an electrical diagram illustrating the arrangement employed for inhibiting operation of the press of Figure 4 when the operator's hand or any earthed object is put in the 10 region to be guarded. The workpiece is located immediately below the guarded region so that it will not itself inhibit operation of the machine. The electrical circuit of Figure 5 is housed at 44 in Figure 4 and 15 is, in many respects, similar to that of Figure 2. The same reference characters are used in Figures 3 and 5 to indicate corresponding elements. In Figure 5, the output of the amplifier 32 is fed to the operating coil 20 48 of a relay having a normally open contact 45 in the circuit from a supply source 46 to the hydraulic operating valve 47 for the press. The output of the amplifier 32, in the absence of any earthed body in the 25 guarded region, energises the coil 48 so closing contact 45. A foot switch 59 is used to complete the circuit when the press is to be operated. If any earthed body is in the guarded region, the relay coil 48 is 30 energised so opening contact 45 and preventing operation of the press. A microswitch 49 is operated by the plunger of the press just before the tool enters the guarded region and completes a circuit in parallel 35 with the contact 45 to prevent the machine being stopped because the presence of the tool is sensed by the electrode system.

Figure 6 illustrates the application of the 40 invention to a moulding machine or press having co-operating die plates 50, 51 carried on platens 52, 53. In this case there are two closed loop electrode systems, of which one is seen at 54. These electrode systems, each having its associated screen, 45 extend around the peripheries of the two platens 52, 53 facing one another. These electrode systems thus serve to detect the presence of any earthed body between the two electrodes. In a moulding machine or 50 press such as is shown in Figure 6, the finally formed articles might be ejected using an air blast and it will be noted that, even if these are metal articles, they will not be electrically earthed whilst being ejected and 55 hence would not give an unwanted or false indication inhibiting operation of the machine.

Referring to Figures 7 and 8, two strip 60 form electrodes 60 are employed with their broader surfaces facing one another. Each electrode is screened by a channel shaped screen 61 extending around the back of the electrode with the two arms 62, 63 of the channel extending forwardly of the front 65 faces of electrodes. It will be noted that

one of the arms 62 of the screen extends further forwardly than the other 63 thereby more closely defining one boundary of the "guarded" region between the electrodes 60 where an earthed body can be detected. The electrodes 60 are connected in parallel 70 to a three-terminal capacitance measuring bridge by co-axial cables 64 and the outer conductors of these cables are connected to the screens 61. The bridge circuit may be similar to that described with reference to Figures 3 and 5.

The electrode and screen systems of Figures 7 and 8 may be mounted on fixed structural elements 66, 67 as shown in Figure 7. Typically such structural elements would be earthed metal elements forming part of the structure of, for example, a machine tool. The screens 61 are electrically insulated from the metal structure but are between the electrodes and the earthed metal structure elements so ensuring that the electrodes are responsive only to the capacitances to earthed bodies between the facing front surfaces of the two electrodes. Although there will be large capacitances between the electrodes and the screens, these are "seen-off" by using a three-terminal measuring circuit and do not affect the response of the circuit to variations in the capacitances between the electrodes and earthed bodies. 85 90 95

As shown in Figure 9 it may sometimes be convenient to mount electrodes 70, 71 with their respective screens 72, 73 on movable guards 74, 75. In the particular construction shown in Figure 9 the electrodes and screens are similar to those of Figures 7 and 8 but are mounted on resilient supports 76, 77. The two guards constitute 100 105 gates which slide in the direction of the arrows 78, 79 and overlap when closed. The electrodes are arranged to face one another when the gates are open, i.e. when maximum sensitivity is required. 110

Figure 10 shows a single closed loop electrode 80 which is shown diagrammatically. This electrode is provided with a screen similar to the screen 81 of Figures 7 and 8 and typically is mounted on a machine tool having a mechanical guard 81. The electrode system, although in the form of a single closed loop, has the plane of the loop in a vertical plane at the rear with top and bottom forwardly extending portions so defining a working region to which access is available from the front and two sides. In the drawing, this is indicated by the various positions of the operator's hand. The screens around the electrodes ensure 115 120 125 that the sensitive region in which earthed bodies are detected extends vertically from the top portion of the electrode to the bottom and, in effect gives three protective "walls"

forming the front and two sides of the aforementioned working region.

WHAT WE CLAIM IS:—

1. A capacitance type object detection system for detecting the presence of an earthed object within an opening forming an entry to a region to be guarded, which system comprises an elongated electrode extending around at least part of the periphery 10 of said opening, the electrode being in the form of a strip with one of its faces facing across said opening, a conductive screen for said electrode extending around the other face of the electrode to surround the whole electrode behind the plane of said one face, and a three-terminal impedance measuring 15 circuit arranged to give an output signal responsive to changes in the capacity between said electrode and earth whilst 20 "seeing-off" any capacitance between the electrode and the screen.

2. A capacitance type object detection system as claimed in claim 1 wherein the electrode extends completely around the 25 opening to be guarded.

3. A capacitance type object detection system as claimed in claim 2 wherein the electrode is in the form of a metal strip extending around the region in which the 30 presence of an earthed body is to be detected, the electrode thereby forming a loop enclosing an aperture lying in one plane, and with the plane of the strip parallel to the axis of the aperture defined by the loop.

4. A capacitance type object detection system as claimed in claim 3 wherein the screen is a strip of slightly greater width 35 than the electrode and extending around the electrode on the outer side thereof.

5. A capacitance type object detection system as claimed in claim 4 wherein the screen has flanges extending inwardly of the aperture to shield the edges of the electrode strip.

6. A capacitance type object detection system as claimed in claim 1 wherein two electrodes are provided facing one another.

7. A capacitance type object detection system as claimed in claim 1 wherein the 50 electrode is curved in the form of an arc so as partially to surround a region to be guarded.

8. A capacitance type object detection system as claimed in either claim 6 or claim 55 7 wherein the or each electrode is in the form of a metal strip and wherein the screen is a strip of slightly greater width than the electrode lying adjacent and parallel thereto.

9. A capacitance type object detection system as claimed in claim 8 wherein the screen has flanges extending adjacent the margins of the electrode strip.

10. A capacitance type object detection 65 system as claimed in any of the preceding claims wherein the or each electrode is covered with insulating material.

11. A capacitance type object detection system as claimed in any of the preceding 70 claims and for use on a machine tool wherein the or each electrode is so positioned or arranged that it cannot be touched by an operator's hand or other earthed body.

12. A capacitance type object detection system as claimed in any of the preceding 75 claims wherein the three-terminal impedance measuring circuit is a capacitance detection device comprising a source of alternating voltage, one terminal of which is earthed and the other terminal of which is connected by a lead, referred to hereinafter as the neutral line, to one input terminal of an alternating current detector the other input terminal of which is connected by the inner conductor of a co-axial cable to said electrode, the outer conductor of the co-axial cable being connected to said screen and to said neutral line and a balancing circuit for feeding alternating current into said detector to balance the alternating current due to the presence of an earthed body having capacitance between the body and said electrode or electrodes.

13. A capacitance type object detection system for detecting the presence of an earthed object comprising a closed loop electrode extending around the region within which the presence of an earthed body is to be detected and a conductive screen extending around the outer side of said closed 90 loop-electrode and closely adjacent thereto so as to lie between the electrode and any surrounding body in combination with a capacitance detection device comprising a source of alternating voltage, one terminal 95 of which is earthed and the other terminal of which is connected by a lead, referred to hereinafter as the neutral line, to one input terminal of an alternating current detector the other input terminal of which is connected by the inner conductor of a co-axial cable to said electrode, the outer conductor of the co-axial cable being connected to said screen and to said neutral line and a balancing circuit for feeding alternating current into said detector to balance the alternating current due to the presence of an earthed body having capacitance between the body and said electrode.

14. A capacitance type object detection 100 system as claimed in either claim 12 or claim 13 wherein the detector comprises a high gain amplifier with a feedback circuit for providing a feedback current to the input of the amplifier.

15. A capacitance type objection detection system as claimed in claim 14 wherein the output voltage from the amplifier is applied to a phase sensitive detector having a 105 110 115 120 125

reference signal derived from the alternating current source.

16. A capacitance type object detection system as claimed in any of the preceding 5 claims and arranged for use with a machine tool having a mechanical guard wherein means are provided responsive to said output signal operative to actuate the mechanical guard when the operator's hand or other 10 earthed body is withdrawn from the guarded region.

17. A capacitance type object detection system as claimed in any of claims 1 to 15 and arranged for use with a machine tool 15 wherein means are provided responsive to said output signal operative to inhibit the operation of the machine tool when the operator's hand or other earthed body is in the guarded region.

18. A capacitance type object detection system as claimed in claim 6 and arranged for use on a machine tool having a mechanical guard comprising two gates movable 20 towards one another to close an opening and wherein two electrodes are arranged on the gates facing across the opening when the gates are apart, the electrodes being connected in parallel to the three-terminal measuring circuit.

19. A capacitance type object detection 25

system as claimed in claim 18 wherein the gates are arranged to overlap when closed and wherein the electrodes are arranged to face one another when the gates are open so as to define a plane in which any earthed body is detected. 35

20. A capacitance type object detection system as claimed in any of claims 1 to 15 and arranged for use in a machine in which two die plates are brought together, wherein two electrodes are arranged around or partly around each of the die plates, the electrode or electrodes around one die plate facing the electrode or electrodes around the other die plate. 40

21. A capacitance type object detection system substantially as described with reference to Figures 1 to 3 of the accompanying drawings. 45

22. A capacitance type object detection system substantially as described with reference to Figures 4 and 5 or Figure 6 or Figures 7 and 8 or Figure 9 or Figure 10 of the accompanying drawings. 50
